ABSTRACT

The Korean Seismic Research Station (KSRS) short-period array was evaluated using data which cover eight-hour time periods daily between May and June 1973. Most of the data is of poor quality due to instrumental problems. The average noise reduction obtained by beaming was about 2 dB better than \sqrt{N} due to the almost continuous presence of propagating coherent noise at the station. The 50% detection body wave magnitude threshold was found to be 4.35 \pm .45 (95% confidence interval) at the epicentral distance of 60°. The 90% detection threshold was found to be 5.42 \pm .45 magnitude units.

INTRODUCTION

This report presents the results of evaluation of a limited sample of digital data from the Korean Seismic Research Station (KSRS). The data consists of 45 digital tapes, with one eight-hour time interval on each tape, and covers the three-month period of May, June and July in 1973. Table 1 gives the dates, time windows and tape numbers for all of the tapes. The three most important observations about the list of 45 tapes are that (1) the eight-hour intervals every other day provide samples for only one-sixth of the total three-month interval, (2) the time of year is limited to late spring and early summer, and (3) the time of day represented by different tapes is highly variable and provides samples for all hours both day and night, although on different days. This implies that diurnal noise variation may be observable, but seasonal variations cannot be observed.

Table 2 gives the list of events from the NEIS bulletin that fall within the time windows contained on the 45 data tapes. The events are distributed around the world in the principal seismic regions. The asterisked events were detected. The nine regions of best sampling on this list are (in order of decreasing sample size) Chile, Kuriles, Alaska, Fijis, Hokkaido, New Guinea, Nevada, Mexico, and New Hebrides. The first, Chile, is represented by 19 events and the last, New Hebrides, contains 5 events.

The Korean short-period array is centered about 150 km east of Seoul, South Korea. It consists of 19 seismometers in the configuration shown in Figure 1. They are located in a pattern of two rings around one central instrument. The numbers shown are the tape channel locations for each seismometer site, and it can be seen that number four is the only one located about halfway between two rings. The diameter of the two rings are 4.25 and 9 km. The greatest spacing of any two pair of instruments is 10 km (between Nos. 11 and 17), and the smallest spacing is 1.5 km (between Nos. 4 and 13). Three principal directional alignments are emphasized in Figure 1. These are 013° (193°), 084° (264°), and 135° (315°).

* These events were detected at KSRS

⁺ These events are off-beam

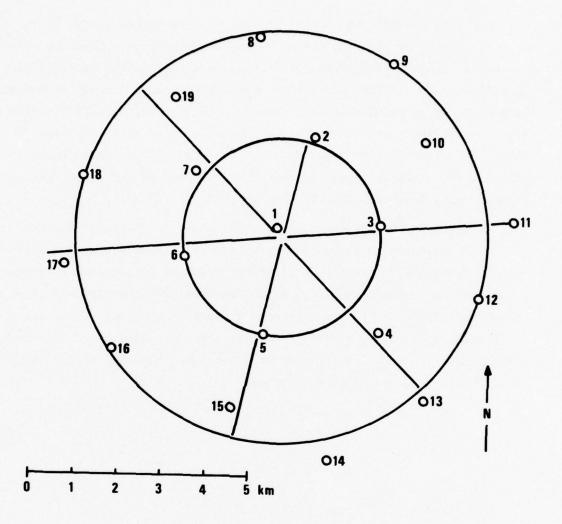

Figure 1. Korean short-period array.

The data quality was highly variable with about one-fourth of the tapes showing as many as eight to twelve channels inoperative or not operating normally. Another problem in data quality was the inadequate digitizing (quantizing) sensitivity for very small signals (noise samples in particular). This produced an angular looking waveform plot and is probably a source of significant errors in power spectrum computation for noise samples. These errors are probably most significant at the higher frequencies (greater than 3Hz) and are probably tolerable at the frequencies of importance in teleseismic work, less than 2Hz.

In addition to inadequate quantizing levels many traces also show distorted waveforms with jumps between several "plateaus" and peculiar looking "one-sided" traces with clipping, dropouts or non-linear compression of amplitudes in one direction. These features are probably associated with functional defects in the on-site data processing systems. There are segments of recordings, however, where the signals and background noise look completely normal. We estimate, however, that less than half of the data is free of some kind of system distortion.

NOISE SAMPLES

Six 320-second noise samples were analyzed to determine the Korean short-period noise characteristics. All noise samples preceded strong events selected by inspecting seismograms to be certain that all 19 seismometers were operating normally. All samples ended about ten seconds before the impulsive start of a clear first arrival P-phase close to the predicted arrival time.

Power spectra of six noise samples are shown in Figure 2. On the top part of the figure the spectra with the highest and lowest absolute noise level are shown. The largest difference between the two curves is about 4 to 5 dB. The lower part of the figure shows the rest of the spectra staggered on the vertical scale to avoid visual crowding. All spectra fall of sharply towards higher frequencies, and show secondary peaks at approximately 2 and 3Hz.

Reduction in noise spectra after beamforming is shown in Figures 3 and 4 for both the Korean and NORSAR comparable arrays. In the case of the NORSAR site the spectral data are "Average Subarray Beam" (Barnard and Whitelaw, 1972, Figure II-2). In both cases, spectral noise reduction is about equal to the square-root of the number of sensors (10 log N for power spectrum).

An analysis of the variation of spectral noise reduction was done for the six noise samples and several different azimuths, and velocities as listed in Table 3. The results are summarized in Figure 5. All fifteen cases listed in Table 3 were considered at each frequency and the median, minimum and maximum were calculated. It is clear from inspection of Figure 5 that beamforming noise reduction produced a median value within one dB of square root of N from 1.0 to 2.0Hz. From about 0.5 to 1.0Hz the median was better than square root of N by 3 to 5 dB. The average improvement over $N^{1/2}$ in the .9 to 1.5Hz range, which is of prime interest in teleseismic

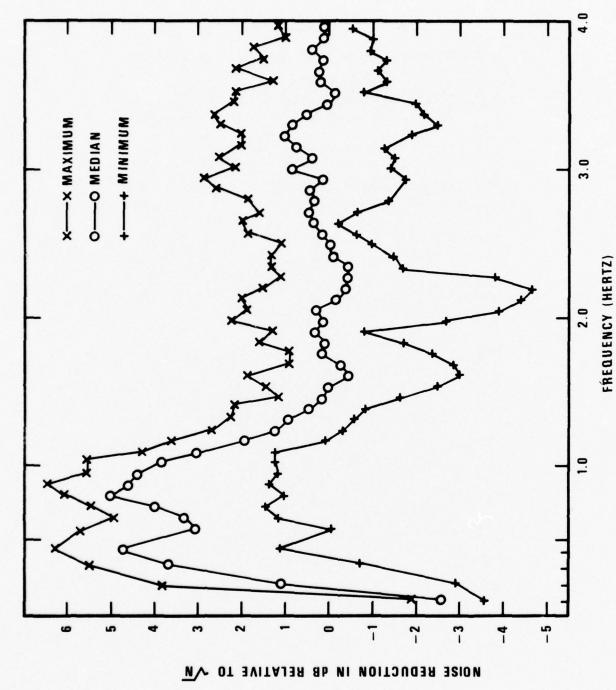

Figure 5. Distributions of spectral noise reduction after beamforming.

P-wave studies, is about 2 dB. The probable explanation for this effect also found by Prahl et al. (1975), is the presence of coherent propagating noise which is often present at coastal stations. As an independent check we also computed the noise reduction from estimates of array cross power spectral matrices and found identical results. The noise reduction is approximately the same for all velocities appropriate to teleseismic P waves. This is not surprising since the delays involved are small compared to the phase delays of slowly propagating 0.5-1.0Hz surface waves. At frequencies lower than .3Hz the long-period noise interferes constructively over the whole array.

Prahl, S. R., Shen, W. W., Whitelaw, R. L., 1975, Preliminary evaluation of the Korean seismological research station short-period array, Texas Instruments ALEX (01)-TR-75-05, Alexandria, Virginia.

PREFORMED BEAM DETECTION

Searches were made in predicted time windows for P-phases using the seven beams which are calculated by the station processor. The beam data channels are as indicated in Table 4.

As a result 114 detections were made from a total NEIS list (Table 2) of 209 events. Table 5 summarizes all 114 detections, giving date, abbreviated geographic region, seismic region, amplitude (in units based on the same conversion constant, 0.488 mµ/count, used for seismometer amplitude) and period. For the purpose of detectability calculation, the data were divided into two groups. The first group includes those events that were within the preformed beam azimuthal windows and the second group includes those events that were in the two azimuth gaps not covered by the preformed beam (080°-100° and 185°-205°) and events at distances greater than 100 degrees. The magnitudes were reduced to the epicentral distance of 60° and sorted into magnitude increment ranges. A maximum likelihood procedure described by Ringdahl (1976) was used to fit a detection probability curve to the observed probabilities of detection derived from Table 2. The results are given in Table 6 and Figure 6. The classification of one event of magnitude 6 was changed from undetected to detected since the failure to detect this event was due to malfunction in the recording system and it would have certainly been detected otherwise.

The body-wave detection thresholds together with their 95% confidence intervals for on-beam events at $\Delta = 60^{\circ}$ were $5.42 \pm .45$ at the 90% level and $4.35 \pm .45$ at the 50% level. The detection thresholds of "all events" and off-beam events are within two standard deviations of this value; therefore, they are not significantly different. The 50% detection thresholds agree well with that derived by Texas Instruments group (Prahl, Shen, and Whitelaw, 1975). The 90° threshold is considerably higher than at other arrays

Ringdahl, F, 1976, On the estimation of seismic detection thresholds, Bull. Seism. Soc. Am., v. 65, p. 1631-1642.

(Dean, 1971; Barnard and Whitelaw, 1972). One can attribute this to the high noise level at KSRS which is about three times the average noise amplitude at NORSAR. Although data quality is often poor, only a few events were not detected because of instrument malfunctions; these do not effect the threshold determination appreciably.

Dean, W. C., 1971, Detection threshold fo the LASA/SAAC system, Seismic Array Analysis Center Report No. 3, Teledyne Geotech, Alexandria, Virginia.

UNFILTERED SIGNAL BEAMFORMING

Fifteen of the best events were selected for unfiltered signal and noise beamforming in the precalculated direction and azimuth of the event. In Table 7 we give the signal loss at beaming and the average wide-band noise reduction in dB. The results show that the signal loss is very small indicating that the signal is similar across the array. The overall noise amplitude reduction is close to \sqrt{N} (12.8 dB). This is probably because the noise cancellation in wide band use is dominated by noise amplitudes at the spectral peak where at the low frequency side the noise reduction is worse than \sqrt{N} while at slightly higher frequencies it is better (see Figures 3 and 5), the overall result is therefore close to \sqrt{N} .

SUMMARY

Evaluation of the Korean Seismic Research Station led to the following conclusions.

- 1.) The average wide band rms noise reduction is about 2 dB better than \sqrt{N} due to coherent propagating noise at frequencies below 1.5Hz. At frequencies above 1.5Hz the noise is incoherent.
- 2.) The 50% body wave detection threshold is at m_b = 4.35 \pm .45 at the epicentral distance of 60°. The 90% detection threshold is at m_b = 5.42 \pm .45. The limits indicated above are at the 95% confidence level.
- 3.) Instrument and system malfunctions reduce the utility and reliability of the data at this array in the May June 1973 time interval greatly.
